### **ABSTRACT**

**BACKGROUND:** The relationship of muscle deoxygenation to maximum workload at peak exercise using near-infrared spectroscopy (NIRS) can provide insight into clinical populations with known exercise intolerance, but there are few studies available. **PURPOSE:** To characterize the relationship between change in muscle deoxygenation (deoxygenated hemoglobin;  $\Delta\text{HHb}$ ) and maximal workload achieved at peak exercise (MW). **METHODS:** 15 males and 3 females (mean $\pm$ SD: 27.28 $\pm$ 13.60 years [age]) underwent a cardiopulmonary exercise test (CPET) on a recumbent cycle ergometer. Measurements at peak exercise included  $\Delta\text{HHb}$  of the left vastus lateralis using NIRS, MW (Watts), and oxygen uptake ( $\text{VO}_2\text{peak}$ ). We regressed  $\Delta\text{HHb}$  on MW at peak exercise as the primary predictor with  $\text{VO}_2\text{peak}$  as a covariate. We used a second order polynomial regression model to test for both linear and quadratic relationships. **RESULTS:** Participant characteristics (mean $\pm$ SD) were as follows:  $\Delta\text{HHb}$  = 12.67 $\pm$ 7.30  $\mu\text{mol}$ , MW = 241.22 $\pm$ 61.82 W, and  $\text{VO}_2\text{peak}$  = 40.71 $\pm$ 9.29 mL/kg/min. A polynomial model including  $\Delta\text{HHb}$ , MW and  $\text{VO}_2\text{peak}$  best characterized the relationship ( $F=3.654$ ,  $p=0.05$ ) where there appears to be an inflection point in the  $\Delta\text{HHb}$ -MW relationship (see Figure 1). Each 30 W increase in workload was associated with 0.74 increase in  $\Delta\text{HHb}$  up to 241 W, after which  $\Delta\text{HHb}$  decreased curvilinearly ( $-0.17^2$ ) with each further increase in 30 W. **CONCLUSION:**  $\Delta\text{HHb}$  increases with incremental workload but appears to attenuate and slightly decrease at greater MW. It is possible that other factors may influence this relationship. Understanding how muscle deoxygenation, MW, and  $\text{VO}_2\text{peak}$  are related at the time of peak exercise, or if other factors are contributing the differences in  $\Delta\text{HHb}$  at higher workloads, may provide a foundation for uncovering the physiological mechanisms of local oxygen uptake in low and high exercise capacity individuals, and to assess exercise-limiting factors in clinical populations.
